Transport Control Protocol for Cognitive Radio Ad Hoc Network

Ashish Manusmare, Ritu Chauhan

Abstract—The rapid demand for wireless communication networks in the last few decades has lead to spectrum scarcity. Hence there is need of efficient spectrum utilization is occurs. Cognitive radio is a novel technology which improve the spectrum resource utilization and allows a cognitive radio transceiver to detect and sense the available spectrum. Cognitive Radio (CR) networks allow users to transmit in the licensed spectrum bands, without degrading the performance of the Primary Users (PUs). Routing in CRN is a challenging task due to the variations in spectrum availability with time and periodic spectrum sensing undertaken by the CR users. In this paper we investigate the effect of TCP in CR ad hoc network environment and proposes multipath routing protocol, that uses on-demand distance vector routing, called Ad hoc On-demand Multipath Distance Vector (AOMDV) Routing Protocol. We analyze its performance using Network simulator (NS-2) software tool. Simulation gives effective result of cognitive radio ad hoc networks and analyzed the parameter delay, throughput and energy.

Index Terms—TCP, UDP, Cognitive Radio Network (CRN), spectrum sensing, AOMDV.

I. INTRODUCTION

Highlight Cognitive radio (CR) technology which aims to improve the spectrum utilization in the licensed frequencies band, and also solve the congestion in the 2.4GHz ISM band. Recent research in this area has primarily focused on spectrum sensing and sharing issues in infrastructure-based networks that relies on the presence of a centralized entity for collecting the spectrum information, deciding the best possible spectrum for use, and allocating transmission schedules to the CR users served by it. The application of CR technology in distributed scenarios is still in a nascent stage. This project proposes a CR routing protocol for ad hoc networks (CRP) that specifically addresses the concerns of end-to-end CR performance over multiple path and the problem of protecting the PU transmissions from interference with limited knowledge of the environment. Cognitive Radio Ad-Hoc Network (CRAHNs) [3] is a new developed technology of wireless communication. The difference to traditional wireless networks is that there is no need for established infrastructure. Since there is no such infrastructure and therefore no preinstalled routers which can, for example, forward packets from one host to another, this task has to be taken over by participants, also called mobile nodes, of the network. Each of those nodes takes equal roles, what means that all of them can operate as a host and as a router. Radio communication systems today are already demonstrating one or more of these capabilities in limited ways. SDRs today provide software control of a variety of modulation techniques, transmission security and even wideband and narrow band operation. A cognitive radio adds both a sensing and an adaptation element to the software defined and software radios. Cognitive Radios embodies four new capabilities in SDR to help enable dynamic use of the spectrum: flexibility, agility, RF sensing, and networking [2].

- Flexibility is the ability to change the waveform and the configuration of a device.
- Agility is the ability to change the spectral band in which a device will operate. Combining both agility and flexibility is the ultimate in “adaptive” radios because the radio can use different waveforms in different bands.
- Sensing is the ability to observe the state of the system, which includes the radio and, more importantly, the environment. It allows a radio to be self-aware, and thus is necessary if a device is to change in operation due to location, state, condition, or RF environment.
- Networking is the ability to communicate between multiple nodes and thus facilitate combining the sensing and control capacity of those nodes. Networking enables group-wise interactions between radios, which can be used for measurements that can provide a better understanding of the environment.

The above added features in Cognitive Radio (CR) network achieve opportunistic assignment of vacant portions of the spectrum to secondary users. Figure 1 below shows the four spectrum management functions in a cognitive radio cycle.

![Fig 1: The Cognitive Radio Cycle](image-url)
undertaken by a node strongly influence the end-to-end performance.

- Spectrum Sharing: The transmissions of CR users must be synchronized with spectrum sharing functionality to prevent multiple users from colliding in overlapping portions of the spectrum. Spectrum sharing provides efficient channel and power allocations to avoid interference caused to the primary network. It also adds an intelligent packet scheduling scheme enabled by a spectrum-aware link layer along with spectrum sensing [3].

- Spectrum Mobility: If the specific portion of the spectrum in use is required by a Primary User, the Secondary User should be switched to another vacant portion of the spectrum. This necessitates efficient spectrum handoff and reliable end-to-end connection management schemes [4].

These spectrum management functions demand novel design techniques spanning virtual to all layers of the of the protocol stack on a single device. Already existing link, transport and network layer protocols designed for standard fixed bandwidth ad hoc networks cannot optimally exploit available radio resources and simultaneously provide all the communication services required for CR ad hoc network. Hence a lot of research is carried out on network and transport layer protocol design to achieve the requirements for cognitive radio ad hoc networks. This paper work evaluates the use of modified protocol referred to as TCP CRAHN on transport layer, in conjunction with AOMDV on network layer in a CR ad hoc network environment.

II. LITERATURE SURVEY

TCP works on the principle of conservation of packets by using the acknowledgements to clock outgoing packets. It further maintains a congestion window to reflect the network capacity. However there are certain issues with standard TCP. One major being circularity i.e., as a connection first starts up causes to have acknowledgements one needs to have data in the network and to put data in the network it needs acknowledgements [4]. Standard or classical TCP thus performs poorly over wireless links due to the additional packet losses caused by node mobility or bad channel conditions. Hence in the recent past many different modified versions of transport protocols have been proposed for wireless ad hoc networks, employing different approaches such as cross-layer or layered approach.

In a CRN environment the Standard TCP offers poor throughput as it treats lost or delayed acknowledgments as congestion. To overcome the problems of standard TCP Tahoe was proposed [5]. It overcomes the circularity problem by employing a slow-start procedure whenever a TCP connection starts or re-starts after a packet loss. Here the sender set the congestion window to 1 and then for each acknowledgment received it increases the Congestion Window by 1, so the number of packets sent in every round trip time (RTT) increase exponentially until there is a loss of a packet which is a sign of congestion [6].

In 1990, V. Jacobson proposed TCP Reno which worked on similar [7] basic principle of Tahoe. It retains ‘slow starts’ and coarse grain re-transmit timer principle as in TCP Tahoe and further adds some intelligence over it so as to detect packet loss earlier and preventing pipeline to be emptied every time for a packet loss. But in case of multiple packet loss condition in one window then RENO doesn’t perform too well and its performance is similar to that of Tahoe [8]. TCP New-Reno is a slight modification over TCP-Reno. It introduced a progressively fast recovery algorithm that could easily recover from multiple losses in a single window, thus avoiding many of the retransmission timeout. It is much more efficient in the event of multiple packet losses [9].

TCP Vegas is another modification of TCP Reno, which extends on the re-transmission mechanism of Reno [10]. Further it is different in congestion avoidance, as it determines congestion by a decrease in sending rate. In [11] an improvement in TCP Vegas is proposed with better BW estimation scheme. The proposed method in comparison to TCP Reno it has better delay bias. Further TCP Vegas has gives efficient use of network resources.

Jian Liu and Suresh Singh in their work in [12], have a thin layer between Internet protocol and standard TCP is implemented so as to correct this problem and maintains high end-to-end TCP throughput. Their proposed ATCP algorithm treats loss due to packet loss and due to congestion differently. It also recomputes the congestion window after every new route recomputation. They propose to improve TCPs throughput by a factor of 2–3. In [13] modification in the congestion window adaptation in the classical TCP based on the available bandwidth estimation is proposed. This approach thwarts erroneously plummeting of transmission rate during spectrum sensing. Conversely, the work fails to consider the impact of network mobility, sensing activity and spectrum switching durations on the congestion control functions.

In [14] TCP CRAHN: a protocol for Cognitive Radio Ad Hoc Networks is proposed. The proposed method incorporates spectrum awareness in the classic TCP protocol. This is achieved by a combination of explicit feedback from intermediate and destination nodes. Here the classical TCP rate control algorithm at the source is made to closely interact with the physical layer channel information, the link layer functions of spectrum sensing and buffer management, and a predictive mobility framework that is developed at the network layer. The work claims to achieve significant improvements in the use of proposed TCP CRAHN as transport layer protocol for CR ad hoc networks.

III. TCP CRAHN

TCP CRAHN is a window-based, spectrum-aware protocol for CR ad-hoc networks, that distinguishes between the different spectrum specific conditions in order to undertake state-dependent recovery actions [14]. TCP CRAHN comprises of 6 states addressing a particular CR network condition namely, Connection establishment, Normal, Spectrum sensing, Spectrum change, Mobility predicted, and Route failure (as shown in Figure 2). Figure 2 below shows the States of TCP CRAHN.

A. Connection Establishment

To obtain the sensing schedules of the nodes in the routing path, TCP CRAHN modifies the three-way handshake in TCP NewReno. First, the source sends SYN packet to the destination. An intermediate node in the routing path appends its ID, a timestamp and other sensing related information to the SYN packet.
The receiver in response to the SYN packet sends a SYN-ACK message back to the source. The sensing information collected for each intermediate node is saved over the SYN-ACK. This process helps the source to know when a node undertakes spectrum sensing and its duration. Finally an ACK is sent by the source to the destination to complete the 3-way handshake process, constituting the connection establishment process. In TCP CRAHN, these collected sensing times from the nodes are dynamically updated.

B. Normal State
This is the default state and is similar to functioning of the classical TCP NewReno. TCP CRAHN enters this state when there is no node in the path engaged in spectrum sensing or when there are no connection breaks or there are no signaled route failures. The differences between TCP CRAHN in the normal state and the classical TCP are as follows. In this stage, TCP CRAHN differs slightly from the classical TCP, in that the congestion event is signaled through an Explicit Feedback Congestion Notification (ECN) generated by the affected node and the feedback through ACK i.e., the ECN and ACK regulates the congestion window.

C. Spectrum Sensing State
To meet the high throughput demand, TCP CRAHN acclimatizes to spectrum sensing through flow control and regulating the sensing time. The flow control helps to prevent buffer overflow for the intermediate nodes during sensing. As in case of no Primary User activity on a given channel and comparatively large sensing times degrade the end-to-end throughput of the channel. Thus TCP CRAHN conservatively reduces sensing time for the nodes that see limited PU activity. To identify a node for adjusting its sensing time, TCP CRAHN ranks the nodes in the path based on the number of times the operational channel was changed due to Primary User activity.

D. Spectrum Change State
This where the TCP CRAHN scales its congestion window rapidly accounting factors such as contention delays and channel errors at the link layer, so that the available spectrum resource is most efficiently utilized. If PU activity is reported to the source through an Explicit Pause Notification (EPN), Spectrum Change state is entered and reverts back to the usual operation on receiving the new channel information through the Channel (CHN) message. It enters into the Route Failure state on the receipt of an ICMP (through Internet Control Message Protocol) message signifying route outages.

E. Mobility Predicted State
TCP CRAHN uses a mobility prediction framework based on Kalman filter-based estimation to address delayed route failure notification problem [14]. This is a virtual state, in which the congestion window is restricted to the spectrum sensing threshold. Finally either the Normal or the Spectrum Sensing state is continued.

F. Route Failure State
This state is entered when an intermediate node sends a destination unreachable message in the form of an ICMP packet and it takes precedence over all the others states. The ICMP is achieved when the next hop node is not reachable or there is no ongoing spectrum sensing based on the last known schedule or no EPN message is received at node signaling a temporary path disconnection due to PU activity. At this stage, the source terminates the current cycle and a fresh TCP connection needs to be formed over the new route.

IV. AD-HOC ON-DEMAND MULTIPATH DISTANCE VECTOR (AOMDV)
AOMDV routing protocol is an extension to the AODV (As-hoc On-demand Vector) protocol for computing multiple loop-free and link disjoint paths [15]. AOMDV finds routes on demand by using a route discovery procedure. In AOMDV, RREQ propagation from the source towards the destination ascertains multiple reverse paths both at intermediate nodes and destination. The routing entries for each destination contain a list of the next-hops along with the corresponding hop counts. A node maintains the advertised hop count for each destination, which is defined as the maximum hop count for all the paths. Loop freedom is assured for a node by accepting alternate paths to destination if it has a less hop count than the advertised hop count for that destination. Multiple RREPs traverse these reverse paths back to form multiple forward paths to the destination at the source and intermediate nodes. The trajectories of each RREP may intersect at an intermediate node, however to ensure link disjointness, each RREP takes a different reverse path to source. AOMDV has three novel features: 1) it has minimum inter-nodal coordination overheads; 2) it guarantees disjoint alternate routes via distributed computation and 3) it computes alternate paths with minimal additional overhead by exploiting already available alternate path routing information. There are three phases of the AOMDV protocol. The first phase is the Route Request, second is the Route Reply and the third phase is the Route Maintenance phase.

- Route Request
The protocol propagates RREQ from source towards the destination. The figure 1 will show the working of AOMDV, which allows multiple RREQ to propagate. The node S has to set a path to the destination node D. So node S in AOMDV broadcasts multiple requests to its neighboring nodes 1 and 2.

- Route Maintenance
In this session, protocol establishes multiple reverse paths both at intermediate nodes as well as destination. Multiple RREPs traverse these reverse paths back to form multiple forward paths to the destination at the source and intermediate nodes. If the intermediate nodes have the route defined for the
destination then they send the RREP to the source node S. The protocol is designed to keep track of multiple routes where the routing entries for each destination contain a list of next hops together with the corresponding hop counts. All the hop counts have the same sequence number then the path with the minimum hop count is selected and all the other paths are discarded. The protocol computes multiple loop-free and link disjoint paths. Loop-freedom is guaranteed by using a notion of “advertised hop count”. Each duplicate route advertisement received by a node defines an alternative path to the destination.

- Route Maintenance Phase

The third phase is the Route Maintenance Phase. In this phase, if the intermediate nodes are not able to receive a response of the HELLO message then they broadcast a Route Error message. After receiving this message all the nodes that use the particular route to reach the destination make this particular route as infinity and inform the source node to run a fresh route discovery. Routing table entry structure of AOMDV as shown in table No.1.

V. PROPOSED WORK

In the proposed work we describe the performance of routing protocol with the spectrum selection, route discovery and route preservation in Network layer, for that we consider the number of nodes for the cognitive ad hoc networks as the primary users (PUs). One of the node initially consider the source node which propagates the number of nodes after some interval of time in the wireless environment. Considering the twenty number of nodes for the implementation, which are connected for the communication with specific channel allocation from source node to the destination node. The route request RREQ is send initially from the source node & after confirmation the Destination node send the route reply RREP. If at the destination node if the problem create the destination send the RERR message to the source node i.e. the discarding of the packets. The following is the steps for the testing the simulation based on routing protocol.

VI. SIMULATION AND RESULTS

The proposed system employs the use of TCP CRAHN along with AOMDV as the network layer protocol. The proposed system is implemented using NS-2 simulator for a CR ad-hoc environment. Following parameters are considered for the implementation of CRAHNs in NS2.

Figure 6 shows the Delay Graph of the system. The delay of the system is negligible and the maximum time delay is within range of 2 ms. Figure 7 shows the energy graph for the system. It can be seen that the energy of the system remains nearly constant throughout the period. Figure 8 shows the throughput of the system. The throughput of the system is almost 100 except for a brief moment where there is a decrease, however this can be neglected.
VII. CONCLUSION

The proposed system employs the use of TCP CRAHN for Cognitive Radio Ad-hoc network environment. The implementation of the TCP CRAHN protocol at the transport layer and AOMDV at network layer gives great results in comparison to classic TCP implementation. The proposed system has a delay of less than 2ms and throughput of nearly 100%. Usually CRAHN is implemented in UDP environment which gives lower values of Throughput and Higher delays due to packet losses, but as we have implemented TCP based CRAHN we are able to reduce the delay and improve the throughput at the same time without increasing the energy consumption in the network.
